Abstract. Decision tree learning is a machine learning technique that allows to generate accurate and comprehensible models. Accuracy can be improved by ensemble methods which combine the predictions of a set of different trees. However, a large amount of resources is necessary to generate the ensemble. In this paper we introduce a new ensemble method that minimise the usage of resources by sharing the common parts of the components of the ensemble. For this purpose we learn a decision multi-tree instead of a decision tree. We call this new approach shared ensembles. The use of a multi-tree produces an exponential number of hypotheses to be combined, which allow better results than *boosting/bagging*. We perform several experiments, showing that the technique allows to obtain accurate models improving the use of resources with respect to classical ensemble methods.
Keywords: Decision-tree learning, Decision support systems, Boosting, Machine Learning, Hypothesis Combination, Randomisation.

1 Introduction

From the different machine learning approaches that are widely applied currently with successful results, decision tree learning [16] is considered a paradigm with an optimal trade-off between the quality and the comprehensibility of the models learned.

A method that has been recently exploited to improve the accuracy of simple classifiers consists in the combination of a set of hypotheses (or ensemble) [3]. Well-known techniques for generating and combining hypotheses are boosting [8, 18], bagging [1, 18], randomisation [4], stacking [19] and windowing [17]. Although accuracy is significantly increased, "the large amount of memory required to store the hypotheses can make ensemble methods hard to deploy in applications"[12]. One way to overcome partially this limitation could be to share the common parts of the components of the ensemble.

In previous work [5], we have presented an algorithm for the induction of decision trees which is able to obtain more than one solution. To do this, once a node has been selected to be split, the other possible splits at this point are suspended and stored until a new solution is required. In this way, the search

* This work has been partially supported by CICYT under grant TIC2001-2705-C03-01, Generalitat Valenciana under grant GV00-092-14, and Acción Integrada Hispano-Austriaca HU2001-19.

space is a multi-tree rather than a tree which is traversed producing an increasing number of solutions for increasing provided time. Since each new solution is built following a suspended node at an arbitrary place in the multi-tree, our method differs from other approaches such as the *boosting* or *bagging* method [1, 8, 18] which induce a new decision tree for each solution. Therefore, a multi-tree is not a forest [10] because a multi-tree shares the common parts of different trees (*shared ensemble*), whereas a forest is just a collection of trees.

Other works have tried to generate a forest of 'different' trees, either semantically/vertically (by changing the weights of examples, e.g. boosting [8, 18], or the sample, e.g. bagging [1]) or syntactically/horizontally (by selecting attribute samples for each tree). In particular, this latter approach has been presented independently by [9, 10], under the name pseudo-randomly selected feature subspaces, and by [20], under the name stochastic attribute selection committees. In both cases the idea is to select pseudo-randomly a subset of attributes, learn a first classifier, then select other subset of attributes, learn a second classifier, and so on. Next, the elements from the set of decision tree classifiers (the forest) are combined. A related technique has been presented by Breiman in [2].

The main aim of both the horizontal and vertical approaches is to obtain a better accuracy in the combination. There have also been attempts to combine horizontal and vertical approaches, such as the work from [21]. In [4] a randomised method have been introduced in the construction of the tree (random split criterion), and has been shown to be competitive w.r.t. boosting and bagging.

In this paper, we focus on the combination of hypotheses from the multi-tree approach in order to obtain accurate models. The use of this structure allow to combine more hypotheses than in other combination methods by using the same resources. Several hypotheses fusion strategies are defined and evaluated experimentally. We also include a comparison between our approach and some well-known ensemble methods.

The paper is organised as follows. In Section 2, we introduce the multi-tree structure. Section 3 discusses different ways to combine the components of a shared ensemble. Section 4 presents several experiments showing that the approach effectively generates accurate models. Finally, Section 5 summarises and presents some future work.

2 Multi-tree structure

In this section we present the multi-tree structure, and we discuss about the different criteria required to construct it.

The construction of decision trees is performed in two different steps [17]:

- **Tree Construction:** In this phase, the whole decision tree is constructed. The process is driven by a splitting criterion that selects the best pair split. The selected split is applied to generate new branches, and the rest of splits are discarded. The algorithm stops when the examples that fall into a branch belong to the same class.

– **Pruning**. This phase consists in the removal of not useful parts of the tree. There are two options: *pre-pruning*, when the process is performed during the construction of the tree, or *post-pruning*, when the pruning is performed by analysing the leaves once the tree has been built.

Thus, decision trees are built in a eager way, which allows the quick construction of a model. However, it may produce bad models because of bad decisions.

In [5] we have defined a new structure in which the rejected splits are not removed, but stored as *suspended* nodes. The further exploration of these nodes after the first solution has been built allows the extraction of new models from this structure. For this reason we call it decision multi-tree, rather than decision tree. Since each new model is obtained by continuing the construction of the multi-tree, these models share their common parts. A decision multi-tree can also be seen as an AND/OR tree [13, 15], if one consider the split nodes as OR-nodes, and the nodes generated by an OR-node exploited as AND-nodes.

To populate a multi-tree, we need to specify a criterion that selects one of the suspend nodes. In [6] we presented and evaluated some possible criteria, such as topmost, bottom, or random. Our experimental results showed that random is a trade-off between speed and quality.

Once the multi-tree has been built, we can use it for two different purposes: to select one or n comprehensible models (decision trees) according to a selection criterion (Occam, MDL, ...), or to use the multi-tree as an ensemble whose components can be combined. In this paper, we address the latter.

Figure 1 shows a decision multi-tree. OR-nodes are represented with an arc and leaves are represented by rectangles. Three different models are exhibited in this multi-tree since two suspended nodes have been exploited.

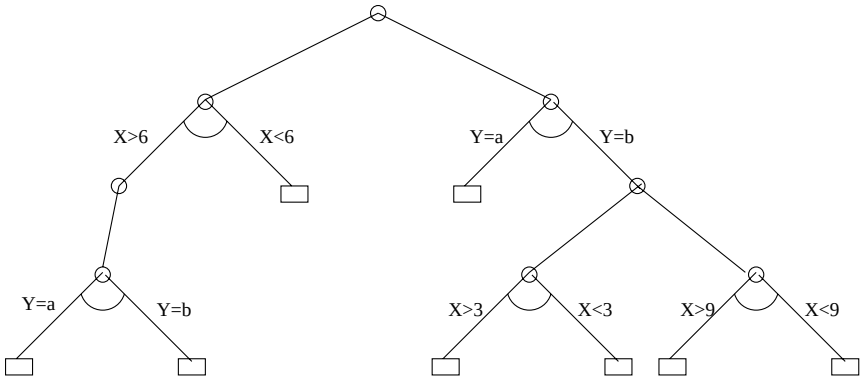

Fig. 1. Selection of a single decision tree from the multi-tree structure.

The decision multi-tree approach presents some interesting features. First, the number of solutions grows exponentially w.r.t. the number of suspended OR-

nodes exploited. Secondly, the solutions share some of their parts. The percentage of the shared quantity depends on the depth of the suspended OR-node exploited. Exploring deep suspended nodes in the bottom areas of the multi-tree causes the generation of models that share many of their conditions, therefore they could be very similar. However, the exploration of OR-nodes in the top positions of the multi-tree produces solutions which are different enough between them.

3 Shared Ensemble Combination

In this section we address how to combine different solutions in a multi-tree. Given several classifiers that assign a probability to each prediction (also known as soft classifiers) there are several combination methods or fusion strategies. Let us denote by $p_k(c_j|x)$ an estimate of the posterior probability that classifier k assigns class c_j for example x. In decision tree learning, the $p_k(c_j|x)$ depend on the leaf node where each x falls. More precisely, these probabilities depend on the *proportion* of training examples of each class that have fallen into each leaf node during training. The reliability of each leaf usually depends on the *cardinality* of the leaf.

Let us define a *class vector* $v_{k,j}(x)$ as the vector of training cases that fall in each node k for each class j. For leaf nodes the values would be the training cases of each class that have fallen into the leaf. To propagate upwards these vectors to internal nodes, we must clarify how to propagate through AND and OR nodes. This is done for each new unlabelled example we want to make a prediction for. For the OR-nodes, the answer is clear: an example can only fall through one of its children. Hence, the vector would be the one of the child where the example falls. AND-nodes, however, must do a fusion whenever different alternate vectors occur. This is an important difference in shared ensembles: fusion points are distributed all over the multi-tree structure. Following [11], we have considered several fusion strategies that convert m class vectors into one combined vector Ω_j:

- **sum**: $\Omega_j = \sum_{k=1}^{m} v_{k,j}$
- **arithmetic mean**: $\Omega_j = \sum_{k=1}^{m} \frac{v_{k,j}}{m}$
- **product:** $\Omega_j = \prod_{k=1}^{m} v_{k,j}$
- **geometric mean:** $\Omega_j = \sqrt[m]{\prod_{k=1}^{m} v_{k,j}}$
- **maximum:** $\Omega_j = \mathtt{max}_k(v_{k,j})$
- **minimum:** $\Omega_j = \mathtt{min}_k(v_{k,j})$

There have been some studies to examine which strategy is better. In particular, [11] concludes that, for two-class problems, minimum and maximum are the best strategies, followed by average (arithmetic mean).

In addition, we have devised some transformations to be done to the original vectors at the leaves before its propagation:

- **good loser** : $v'_{k,j}(x) = \sum_j v_{k,j}(x)$ if $j = \mathtt{argmax}(v_{k,j}(x))$ and 0 otherwise
- **bad loser:** $v'_{k,j}(x) = v_{k,j}(x)$ if $j = \mathtt{argmax}(v_{k,j}(x))$ and 0 otherwise.

– **majority:** $v'_{k,j}(x) = 1$ if j= `argmax`$(v_{k,j}(x))$ and 0 otherwise.
– **difference**: $v'_{k,j}(x) = v_{k,j}(x) - \sum_{i \neq j} v_{k,j}(x)$

For example, the following table shows the results of applying the transformations to two vectors.

Original	Good loser	Bad loser	Majority	Difference
{ 40, 10, 30 }	{ 80, 0, 0 }	{ 40, 0, 0}	{ 1, 0, 0 }	{ 0, -60, -20 }
{ 7, 2, 10 }	{ 0, 0, 19 }	{ 0, 0, 10 }	{ 0, 0, 1 }	{ -5, -15, 1 }

In the next section, we show an experimental evaluation of these fusion and transformation methods for problems with more than two classes.

4 Experiments

In this section we present an experimental evaluation of our approach, as it is implemented in the SMILES system [7]. SMILES is a multi-purpose machine learning system which includes, among many other features, the implementation of a multiple decision tree learner.

For the experiments, we have used GainRatio [17] as splitting criterion and we have chosen a random method [6] for populating the shared ensemble (after a solution is found, one suspended OR-node is woken at random). Pruning is not enabled.

The experiments were performed in a Pentium III-800Mhz with 180MB of memory running Linux 2.4.2. We have used several datasets from the UCI dataset repository [14]. Table 1 shows the dataset name, the size in number of examples, the number of classes and the number of nominal and numerical attributes.

#	Dataset	Size	Classes	Nom.Attr.	Num.Attr.
1	Balance-scale	625	3	0	4

Table 2. Comparison between fusion techniques.

Table 2 shows the mean accuracy and the standard deviation using the different fusion techniques introduced in Section 3 for each dataset. We summarise the results with the geometric means for each technique.

The techniques studied are *sum*, *product*, *maximum*, *minimum*, and *arithmetic mean*, all of them using the original vectors. We do not include in the table the experiments with *geometric mean* because they are equivalent to the results of *product*. The multi-tree has been generated exploring 100 suspended OR-nodes, so giving thousands of possible hypotheses (with much less required memory than 100 non-shared hypotheses). According to the experiments, the best fusion technique is *maximum*. Thus, we will use this fusion method to study the effect of applying the transformations on the vector.

Table 3, illustrates the results on accuracy using the *original* vector and the *good looser*, *bad looser*, *majority* and *difference* transformations. According to these experiments, all transformations get very similar results, except from *majority*. We will use the combination *max + difference* in the following experiments.

	Max + Orig		Max + Good		Max + Bad		Max + Majo.		Max + Diff.

4.2 Influence of the size of the multi-tree

Let us study the influence of the size of the multi-tree, varying from 1 to 1,000 OR-nodes explored. Table 4 shows the accuracy obtained using the shared ensembles depending on the number of OR-nodes opened. The results indicate that the further population of the multi-tree allows to improve the results of the combination.

4.3 Comparison with other ensemble methods

Figure 2 presents a comparison of accuracy between our method (*multi-tree*), *boosting* and *bagging* (all of them without pruning), depending on the number of iterations. We have employed the Weka[1] implementation of these two ensemble methods.

Although initially our method obtains lower results with few iterations, with a higher number of iterations it surpasses the other systems. Probably the slow increase of accuracy in the multi-tree method is due to the random selection of the OR-nodes to be explored.

Nevertheless, the major advantage of the method is appreciated by looking at the consumption of resources. Figure 3 shows the average training time depending on the number of iterations (1-300) for the three methods. Note that the time increase of *bagging* is linear, as expected. *Boosting* behaves better with high values because the algorithm implemented in Weka trickily stops the learning if it does not detect a significant increase of accuracy. Finally, SMILES presents a

5 Conclusions

This work has presented a novel ensemble method. The main feature of this technique is the use of a structure called multi-tree that allows to share common parts of the single components of the ensemble. For this reason we call it *shared ensemble*.

Several combination methods or fusion strategies have been presented, as well as class vector transformation techniques. The effectiveness of these methods has also been examined by an experimental evaluation. We have also investigated the importance of the size of the multi-tree w.r.t. the quality of the results obtained.

Finally we have compared the new ensemble method with some well-known ensemble methods, namely *boosting* and *bagging*. The accuracy results for the new method are quite encouraging: although initially, our results are below the two methods, when the number of iterations is increased, the new approach equals and even excels the other methods. Nevertheless, it is in the use of resources where the shared ensembles represent an important advance, as we have shown.

As future work, we propose the study of a new strategy for generating trees different from the current random technique we have employed to explore OR-nodes, probably based on the semantic discrepancy of classifiers. This technique would provide a way to improve the results of our ensemble method with few iterations.
